Vascular anomalies: review of classification, clinical and therapeutic aspects

Anomalias vasculares: revisão da classificação, dos aspectos clínicos e terapêuticos

DOI: http://www.dx.doi.org/10.5935/scd1984-8773.20191131445

ABSTRACT

Vascular anomalies correspond to a broad spectrum of changes that fall into two main groups: 1) vascular tumors, which represent proliferative lesions, and 2) vascular malformations, caused by ectasia in vessels, whether capillary, venous or lymphatic. This article reviews the main vascular anomalies observed in dermatological practice, their main classifications and available treatments, focusing on the use of lasers and intense pulsed light to lighten cutaneous vascular lesions, especially those resulting from malformations.

Keywords: vascular Malformations; Hemangioma; Vascular neoplasms; Laser therapy; Intense pulsed light therapy; Dermatology

INTRODUCTION

Vascular anomalies have a broad clinical spectrum, from an aesthetic-only cutaneous manifestation to life-threatening lesions. They predominate in children and young adults and can be classified into proliferative lesions (tumor) and vascular malformations.1,2 Distinguishing these lesions is difficult due to their phenotypic diversity, and, not infrequently, the term “hemangioma” is misused to describe vascular malformations.1,3 Due to the large number of diseases that constitute vascular anomalies, we review those of primary dermatological interest as well as their main therapeutic approaches.
Classification of vascular anomalies

The oldest classification of vascular anomalies was described in 1863 by Virchow, who divided them into angioma simplex, cavernous angioma, racemic angioma, and lymphangioma, considering the pathology of the lesions. In 2018, ISSVA presented the evolution in the classification of these anomalies, with the identification of new genes implicated in some diseases (Chart 1). Also according to ISSVA, there are some provisionally unclassified vascular anomalies because they are not defined as tumors or malformations or because they have clinical and pathological characteristics still incompletely understood. Examples are: intramuscular hemangioma; angiokeratoma; sinusoidal hemangioma; acral arteriovenous tumor; multifocal lymphangioendotheliomatosis with thrombocytopenia/cutaneous angiomatosis with thrombocytopenia; PTEN hamartoma of soft tissue/soft tissue angiomatosis; fibro-adipose vascular anomaly.

It is essential to differentiate between malformations and vascular tumors that appear during childhood since the diagnosis can change the treatment direction and the outcome for the patient. It is also essential to know that vascular anomalies can have various effects on the child’s psychosocial development because depending on their location, extent, and severity, it can cause significant aesthetic disfigurement.

1.1. Vascular tumors

Vascular tumors are neoplasms characterized by increased endothelial cell proliferation. Lesions usually overgrow, and most are not present at birth, following a phase of proliferation and subsequent involution. They can be classified as benign, locally aggressive, and malignant, based on cellular behavior.

Infantile hemangioma, congenital hemangioma, tufted angioma, and pyogenic granuloma are examples of benign vascular tumors. Kaposiform hemangioendothelioma (KHE) exemplifies locally aggressive or borderline tumors. Angiosarcoma and epithelioid hemangioendothelioma, in turn, represent malignant vascular tumors, which we don’t address here.

1.1.1. Infantile hemangioma

Infantile hemangioma (IH) is the most common benign vascular tumor among children, with an incidence of 4% to 10%, most frequently observed in the cervicofacial region (80% of cases), in women, and in Caucasians. It may have superficial (te-
Vascular anomalies: review of classification, clinical and therapeutic aspects

1.1.2. Congenital hemangioma

Congenital hemangioma is a vascular tumor that is completely formed at birth and has no postnatal proliferation. It can be identified intrauterine by obstetric ultrasound, usually in the third trimester of pregnancy. It presents as solitary exophytic plaques or masses of violet color and telangiectatic surface and may have hypochromic areas in the center and periphery. Immunohistochemistry is negative for GLUT-1 in these tumors.2

According to natural history, it is classified as rapidly involuting, partially involuting, and non-involuting.1 The treatment of this hemangioma depends on its size, location, and presence or absence of associated complications, such as ulceration, bleeding, and pain. The application of pulsed dye laser can improve the superficial aspect of the lesion and has applicability in residual lesions of tumors that did not completely regress.2

1.1.3. Tufted angioma

Tufted angioma (TA) is a rare and benign vascular tumor, also known as Nakagawa’s angioblastoma or progressive capillary hemangioma. It is most commonly located in the cervical region, shoulder, and upper trunk. Few cases are present at birth or associated with hyperhidrosis or hypertrichosis.1 It presents a risk of association with the Kasabach-Merritt phenomenon, in which severe thrombocytopenia with mild to moderate coagulopathy occurs. There are no effective treatments for TA, and the use of interferon alfa (IFN-alpha) and laser is described.2

1.1.4. Pyogenic granuloma
Pyogenic granuloma is a common benign vascular tumor. Also described as lobular capillary hemangioma, most are acquired and manifest as an erythematous nodule or papule, usually with a scaly collar and bleeding surface. It can be localized in any region of the skin and does not involve spontaneously. Therapeutic options include the use of topical timolol, electrocoagulation, laser, cryotherapy, and surgical exeresis.2

1.1.5. Kaposiform hemangioendothelioma
Kaposiform hemangioendothelioma (KHE) is a rare, locally aggressive vascular tumor. Some authors consider KHE and tufted angioma (TA) as spectra of the same disease.

KHE is present at birth or early in childhood and is more frequent in the trunk, extremities, and retroperitoneal region. Clinically, it is observed as an erythematous-brown macula or plaque that evolves into a poorly defined tumor of hard consistency, similar to tufted angioma. It is an immunohistochemical negative GLUT-1 tumor.2

Like TA, KHE is at risk of association with Kasabach-Merritt phenomenon.2

1.2. Vascular Malformations
Vascular malformations are caused by an alteration in angiogenesis during the embryological period, presenting vascular ectasia with normal endothelial growth.1,2 They affect 0.3% to 0.5% of the population and are present at birth in 90% of cases. Also, they increase in length following the child’s growth without spontaneous involution.1,2,6 Although usually sporadic, vascular malformations may be familial and genetically determined.6

In 2018, Al-Olabi et al. studied sporadic vascular malformations with excluded genetic causes, sequenced the DNA from the tissue of patients with vascular lesions, and found the presence of multiple mosaic-activating variants in four genes of the RAS/MAPK pathway (KRAS, NRAS, BRAF e MAP2K1), commonly activated in cancer cases. They then tested the use of vemurafenib, a BRAF inhibitor, in an animal model with mutations in the RAS/MAPK pathway (KRAS, NRAS, BRAF e MAP2K1), commonly activated in cancer cases. They then tested the use of vemurafenib, a BRAF inhibitor, in an animal model with mutations in this pathway, and observed improvement in vascular malformations in this pathway, and observed improvement in vascular malformations.

Vascular malformations are divided into four groups: simple malformations, combined malformations, malformations of major named vessels, and malformations associated with other anomalies (bone, soft tissue, visceral).1

1.2.1. Simple malformation
They are malformations composed of only one type of vessel: capillary, lymphatic or venous.

1.2.1.1. Capillary malformations
Capillary malformations consist of dilation of capillaries and/or postcapillary venules and mainly affect the skin and mucosa. They present from birth and generally persist throughout life. They may darken and become thicker as the child grows, manifest in isolation or be associated with increased soft and bone tissue.3,5

1.2.1.1.1. Port-wine stain
The Port-wine stain is a simple capillary congenital vascular malformation, usually of unilateral, segmental manifestation, without involution tendency.2,8 Also known as flame nevus, it is commonly mistakenly referred to as “flat hemangioma”. It has no predilection for sex and is less frequent in Asian and African American populations. It is the second most common congenital vascular malformation in childhood, characterized by capillary and venous ectasia in the dermis, which results in increased hemoglobin in the skin, giving it a more reddish or purpuric pigmentation.8,9

The Port-wine stain originates from irregularities in neural development and genetic mutations, which may be familial or sporadic.6,8,9 It was recently associated with a mosaic mutation in GNAQ gene.2,5

Mutations in the expression of RASA 1 and vascular endothelial growth factor (VEGF) have also been implicated in the pathogenesis and progression of these lesions.5,10

In 1986, Smoller and Rosen documented a significant reduction in perivascular nerve fiber density in Port-wine stain compared to healthy skin.11 Because neural mechanisms regulate cutaneous vascular flow, changes in nerve distribution would affect the development of these lesions.8,9,11

They are often seen in the distribution of dermatomes, involving one or more branches of the trigeminal nerve, when located on the face.8,10

It presents as a pink, red or purplish-colored macula or plaque on the skin that progressively darkens if not treated early and becomes hypertrophic or nodular with age in approximately two-thirds of patients at 50 years of age.8,10

Although it can be located in any region of the body, the face and cervical region are the most affected areas, especially in the distribution of dermatomes V1 (upper third of the face, innervated by the ophthalmic branch of the trigeminal nerve) and V2 (centrofacial region, innervated by the maxillary branch of the trigeminal), and, when present in these topographies, causes marked disfigurement.2,8

Port-wine stains located on the face may be associated with changes such as jaw hypertrophy, increased lip volume, bite deformity, and spontaneous gingival bleeding.7

When located on the face and neck, these stains respond better to laser treatment compared to those in other body areas.12 The thicker lesions represent great therapeutic difficulty. Therefore, treatment should be conducted early, before thickening and as a way to prevent the development of psychosocial problems resulting from the functional or aesthetic impairment that the lesions cause.8,13

The possibility of recurrence or aggravation of capillary malformation even after its treatment should also be considered. Michel et al. reported recurrence in 16.3% of patients with Port-wine stain treated with pulsed dye laser and noted that in children under 10 years of age there was no recurrence of the lesion.14

Port-wine stain manifests itself or in association with other changes, such as Sturge-Weber syndrome, Klippel-Trenaunay syndrome, and Proteus syndrome.2
1.2.2. Malformations of major named vessels
Malformations of major named vessels affect large-caliber veins, arteries, or vessels, usually axial. Congenital arteriovenous fistulas and persistent embryonic vessels are included in this group of malformations.1
Although they represent a significant clinical impact, they have few dermatological manifestations.

1.2.3. Combined malformations
Combined vascular malformations associate two or more malformations in the same lesion. Examples are: capillary and venous malformations; capillary and lymphatic malformations; venous and lymphatic malformations; capillary, lymphatic and venous malformations; capillary, lymphatic, venous and arteriovenous malformations.5

1.2.4. Vascular malformations associated with syndromes
Vascular malformations, whether simple, major named vessels, or combined, may be associated with bone, soft tissue, or visceral abnormalities.3
Chart 2 shows the principal syndromes of dermatological interest.
Although there are different therapeutic alternatives described for the treatment of cutaneous vascular malformations, such as percutaneous sclerosis, surgical resection, laser therapy, or a combination of them, there is not yet a method that guarantees the permanent cure of these lesions. Thus, their treatment is still a challenge to physicians.

1.2.5. Use of lasers and lights in vascular malformations
The word “laser” is an acronym for Light Amplification by Stimulated Emission of Radiation.17 Its use in medicine began in the 1960s when Leon Goldman created the ruby laser to treat skin lesions.9
Before its use to treat cutaneous vascular malformations, local and systemic therapies were applied, such as hypertonic glucose injection, monoethanolamine oleate injection (Ethamolin, Farmoquímica S/A, Rio de Janeiro, Brazil) associated with glucose, mornhuate sodium injection, aethoxyklerol injection, ethanol injection, surgical excision, corticosteroid use, interferon, cryotherapy, arterial embolization, beta therapy, and bleomycin, with varied responses.16,18
Lasers and other light sources represent a breakthrough in dermatology for both cosmetic and non-cosmetic applications. They have been increasingly used to remove or lighten many vascular lesions that were once considered untreatable.13,19,20
The laser is considered the gold standard for treatment of cutaneous capillary malformation. However, its indication to treat hemangiomas remains controversial, and it is not recommended in arteriovenous malformations treatment.9,17,21
In the 1970s, the argon laser, which emits a continuous beam of blue-green light with wavelengths between 488nm and 514nm, was widely used to lighten cutaneous vascular lesions, but pigmentary changes and scarring were frequent due to the
Non-selective effects of this laser in the tissues.

Ablative lasers such as carbon dioxide (CO2) 10,600nm and erbium:yttrium-aluminum-garnet (Er:YAG) 2,940nm lasers have also been used for this purpose. Although they did not reach the vessels, they aimed at destroying the lesion by absorbing laser energy by water from adjacent tissues. The 511nm and 578nm copper vapor laser represented an improvement over those already used. However, pulsed dye laser has replaced other lasers in the treatment of Port-wine stains.

More recently, longer wavelength lasers - 755nm alexandrite laser; long pulse 1,064-nm neodymium-doped yttrium aluminum garnet (Nd:YAG) laser - have been used to treat vascular lesions with the advantage of deeper penetration in the skin.

In 1983, Anderson and Parrish developed the theory of selective photothermolysis, allowing the understanding of the interaction between laser and treated tissue. The authors demonstrated that target chromophores selectively absorb specific wavelengths of light and produce thermal energy, enabling selective destruction of lesions with minimal damage to adjacent tissues.

In vascular lesions, the target chromophores are oxyhemoglobin and deoxyhemoglobin, which absorb visible wavelengths of 400 to 780nm, with absorption peaks between 542 and 577nm.

Port-wine stains were the most studied vascular malformations in laser therapy.

### 1.2.5.1. Pulsed dye laser

Pulsed dye laser (PDL) emit lights of wavelengths between 585nm and 600nm and penetrate to a depth of up to 1.8mm. They were introduced in 1989 and revolutionized the therapy of cutaneous vascular lesions, becoming the method of choice for treating vascular malformations such as Port-wine stains.

Its active medium is a fluorescent dye, which may be rhodamine 6G, fluorescein, coumarin, stilbene, umbelliferone, tetratene, or malachite green.

Older PDLs had a pulse duration of 0.45ms. Later models were developed with a longer pulse duration. Because they do not penetrate deep into the skin, their use became limited in the treatment of deeper localized lesions. Most patients require multiple sessions to improve Port-wine stains, yet not always achieving complete elimination of the lesion. Its main adverse event is the formation of purpura, which usually lasts between five and 14 days.

There is a heterogeneity in the response of cutaneous vascular malformations to available therapies, and some factors that influence the unpredictability and resistance to pulsed dye laser treatment are described (Chart 3). Centrofacial lesions, located in the V2 dermatome pathway, have a lower response than those located in the upper and lower thirds of the face, corresponding to V1 and V3 dermatomes, respectively. Also, up to one-third of patients do not respond to treatment despite multiple sessions. Leg and hand lesions are less responsive to PDL treatment compared to facial injuries.

The topical use of rapamycin and imiquimod showed antiangiogenic effects with encouraging results in improving the lightening of Port-wine stains when associated with pulsed dye laser.

Cardoso et al. described, in 2006, the use of PDL to treat tufted angioma, which resulted in significant improvement of local pain and partial reduction of lesion size.

In 2007, Chapas et al. first described the efficacy and safety of treating Port-wine stains with the high-energy pulsed dye laser in children under six months of age. Responses from 49 children submitted to 595nm V Beam® laser associated with dynamic cooling with cryogen tetrafluoroethane and energy ranging from 7.75 to 9.5J/cm² were assessed. This study showed good laser tolerance without atrophy or residual skin scarring and demonstrated the importance of early initiation of treatment of these malformations. Bae et al. evaluated the outcome of the use of bipolar radiofrequency (RF) associated with pulsed dye laser and pointed out RF as an alternative for the treatment of Port-wine stains resistant to therapy with PDL alone in adults.

### 1.2.5.2. Neodymium:yttrium-aluminum-garnet laser

Adapted from the International Society for the Study of Vascular Anomalies (2018)
The neodymium:yttrium-aluminum-garnet (Nd:YAG) laser has a wavelength of 1,064nm. It acts by selective photo-coagulation, and its great advantage is the greater depth of tissue penetration when compared to other lasers in the treatment of vascular lesions. It can penetrate the skin up to 4mm to 6mm, and it is also used for the treatment of Port-wine stains. The laser energy is transmitted through the superficial tissue layers and distributed to the deepest layers.

Long pulse or continuous Nd:YAG lasers have been the method of choice for the treatment of venous malformations due to the wide experience and good results of their use. Although most body tissues do not absorb this wavelength, pigmented tissues do absorb this wavelength better than unpigmented ones.

Also, though the Nd:YAG laser has been shown to be effective in treating deep vascular lesions, it should be considered that its use at fluences slightly above the minimum purpuric dose may lead to complications such as scarring and dyschromia.

Figure 2 shows an example of scar formation after the use of long pulse 1064nm Nd:YAG in hypertrophic capillary malformation located in the upper left lip.

Alcântara-González et al. studied the efficacy and safety of using pulsed dye laser combined with Nd:YAG laser, showing good results in 30 patients aged 8 to 65 years who had mucous and cutaneous venous malformations.

Van Drooge et al. presented, in 2013, the first case series showing the long-term effect of the long pulse 1.064nm Nd:YAG laser on the treatment of hypertrophic areas in Port-wine stains. When evaluating the outcome in 32 patients with a mean age of 51.4 years, followed after a mean of 37 months from the last laser treatment, they observed good and excellent response in 91% of the hypertrophic areas and 63% of color improvement of the lesions treated, with report of hypopigmentation and residual scar in seven and 14 participants, respectively.

Liu et al. assessed the role of the long-pulse, high-energy 1.064nm Nd:YAG laser in the treatment of isolated PDL-resistant Port-wine stains in 20 patients aged 16 to 46 years. The authors observed lightening over 90% of the lesions in 20% of participants, suggesting that the long-pulse 1.064nm Nd:YAG laser may be promising in the treatment of capillary malformations non-responsive to PDL.

In 2017, Murthy et al. studied the response of long-pulse Nd:YAG laser treatment to cutaneous vascular malformations excluding Port-wine stains and showed good to excellent results in 66.7% of the patients assessed, with a mean of 4.6 laser sessions per patient. Most lesions were located in the head and neck (48%) and extremities (31%). They concluded that the laser used in the study is a therapeutic option in the management of symptomatic and stigmatizing lesions resulting from vascular malformations in children and adolescents.

A prospective controlled study that sought to investigate the efficacy and safety of double wavelength laser (595nm pulsed dye laser + 1.064nm Nd:YAG laser) in the treatment of Port-wine stains showed no significant difference in outcome compared to treatment with pulsed dye laser alone.

Source: Savas, Ledon, Fuma, Chacon, Neuri (2013).
Nd:YAG laser has also been used to treat angiokeratomas. Figure 3 shows satisfactory response of lesions located on the buttocks, with reduced bleeding and local infections and consequent improvement in the patient’s quality of life.

1.2.5.3. Potassium-titanyl-phosphate laser

The potassium-titanyl-phosphate (KTP) laser uses a 1.064nm Nd:YAG laser source, whose frequency is doubled using a KTP crystal, producing 532nm wavelength green light. KTP has already been used to treat vascular lesions with good results.

A study comparing PDL with KTP laser found that it left less purpuric lesion immediately after treatment, although patients reported higher pain intensity with KTP.

Kwiek et al. evaluated the response based on comparing three-dimensional photographs of 44 patients with facial capillary malformations treated with doubled frequency 532nm Nd:YAG laser (KTP) and concluded that 77.3% of them had at least a 50% improvement in lesion lightening, with a mean of 7.1 sessions per patient.

1.2.5.4. Intense pulsed light

Intense pulsed light (IPL) is a non-coherent, high-intensity, polychromatic light source that emits light in a spectrum spanning 400nm to 1,200 nm wavelengths. It resembles the laser by the mechanism of action based on selective photothermolysis but differs from it by the possibility of selecting pulse duration and wavelength using filters.

IPL is an effective treatment modality for a growing range of dermatological diseases, and it may represent a treatment of choice in some situations. In the pediatric population, different vascular lesions have been treated with IPL, including Port-wine stains. Greater variability in pulse duration and fluency makes IPL useful in treating vessels of varying diameter and depth.

In 2014, Adatto et al. studied the response of IPL in the treatment of Port-wine stains in 18 participants with Fitzpatrick skin phototypes to IV and a mean age of 32.1 years. The treatment was performed with two-wavelength tip: 500nm to 670nm and 870nm to 1200nm (LuxGT™; Palomar Medical Technologies, Inc., Burlington, MA, USA) to achieve higher vessel specificity and avoid absorption by melanin. Response analysis was based on qualitative (subjective improvement scale, based on comparison of patient photographic records) and quantitative (erythema and pigmentation measurements in treated lesions using the photometric scale using DermaType™; Palomar Medical; Technologies, Inc.) evaluations. The study showed efficacy and safety of the IPL use in the treatment of Port-wine stains in various anatomical locations, with minimal adverse events: transient pain, erythema, scabbing, and purpura.

Camploni et al. describe in 2011 the efficacy of the IPL use in the treatment of vascular lesions, solar lentigos, and actinic keratoses in 85 patients and concluded that IPL is an effective and safe measure for the treatment of these lesions, with better results observed in patients with Fitzpatrick skin phototypes I and II.

Evidence suggest that IPL is a safe and effective modality for the treatment of capillary malformations. It may be especially useful for darker, more vascularized areas, but with minimal or absent nodular lesions. Figure 4 shows good results obtained with the use of IPL in the treatment of Port-wine stain located on the face.

Faurschou et al. included, in a 2011 review, five randomized controlled trials involving patients with Port-wine stain to assess efficacy, adverse events, and satisfaction of participants after treatment with pulsed dye laser (PDL), long pulse Nd:YAG laser, and intense pulsed light (IPL). All studies showed lightening of lesions within three months of treatment. Adverse events described included pain, edema, hypo and hyperpigmentation, scabbing, blistering, hypertrophic scarring, and pyogenic granuloma. Participants preferred the PDL over the IPL result. It was also observed preference to the Nd:YAG laser when compared with the PDL, considering the shorter purpura duration time; PDL associated with cooling was preferred to PDL alone.
Although laser and other light sources represent effective measures in the treatment of cutaneous vascular malformations, some care must be taken to avoid undesirable effects with their use. Table 4 presents measures to be adopted to reduce the risk of laser and intense pulsed light complications, based on the literature and clinical practice.37

### 1.2.5.5. Photodynamic therapy

Photodynamic therapy (PDT) is a photochemical reaction between a light source and a photosensitizing drug that produces reactive oxygen species (ROS) and induces cell death. Its first use was directed to the treatment of non-melanoma skin cancer and preneoplastic skin lesions. Some studies have shown that PDT can cause endothelial injury, vasoconstriction, thrombus formation, and blood flow stasis.10

In 2011, Xiao et al. assessed the outcome and complications of photodynamic therapy following intravenous use of hematoporphyrin monomethyl ether (HMME) photosensitizer followed by the application of a copper vapor laser on Port-wine stains in 507 Chinese participants. This study showed that in 29.8% of cases there was lightening higher than 50% in the treated lesions and 10% of participants had complications such as blistering, scabbing, eczema, hypo and hyperpigmentation, and photoallergy. The authors suggest PDT as a therapeutic option for Port-wine stains, especially in patients with high Fitzpatrick skin phototype and nodular vascular lesions.38

Although the role of PDT in vascular malformations treatment has been studied, its efficacy and safety have not been well established for this purpose.

The identification of somatic mutations in vascular anomalies is changing the understanding of these lesions, with potential targets for new pharmacotherapies being discovered.39

### CONCLUSION

Vascular anomalies have a significant physical and psychological impact on patients. Knowledge of their charac-
Chart 4: Avoiding Complications with Laser and Light Sources

Know Your Laser Device - don’t remember parameters and don’t use preset settings from experiments with other laser devices.

Make sure your device is calibrated and always perform a maintenance routine.

Never shoot a laser without eye protection and on-site fire precautions.

Be sure to leave lasers and light fixtures in sleep mode before removing goggles.

Be aware of the endpoint you wish to obtain to avoid the appearance of:

- Nikolsky sign * (usually 5 minutes after firing)
- Second and third degree burns;
- Crescent Moon lesions;
- Charring fabric;
- Metallic gray pallor;
- Patient with severe pain during procedure.

Use active skin cooling as a means of reducing pain and the risk of burns.

Watch out for increased risk of complications by avoiding:

- Very high power flow or parameters in non-ablative devices;
- Inadvertent staking pulses.

Properly position and align the laser/ intense pulsed light handpiece, and cryogen to reduce risk of burns.

* Sinal de Nikolsky: descolamento epidérmico da derme subjacente, ao ser exercida pressão lateral na área afetada.

Characteristics and classifications is essential to establish the correct diagnosis and initiate appropriate and early treatment, resulting in a better quality of life for patients. Psychological damage can be avoided if treatment is instituted before school age and before the onset of interaction with other children. With the introduction of laser use and the understanding of selective photothermolysis, there has been a considerable advance in dermatological therapy, especially with the use of pulsed dye laser for capillary malformations. Although numerous treatment options for vascular anomalies are available, and many have been investigated in the literature, therapeutic decision-making is still mainly based on expert opinion. In a not too distant future, we expect these cases to be conducted more successfully, with the use of different combinations of laser and other light sources, alone or in association with antiangiogenic agents and, promisingly, gene therapy when needed and well indicated.
Vascular anomalies: review of classification, clinical and therapeutic aspects
